LYING WITH STATISTICS AND VISUALIZATIONS

http://www.marktaw.com/blog/TheTriangleProblem.html
The image you've shown is a classic example of a geometrical illusion often called the "missing square puzzle" or "vanishing square illusion." It appears to show a paradox where rearranging the parts of a figure results in a different amount of area, even though the parts themselves are the same.

This illusion is achieved by the subtle reconfiguration of shapes that are not quite as they seem. The four shapes in the first triangle are rearranged to create the second figure. However, the first figure is a little over 32 square units (if we assume each square on the grid is 1 square unit), while the second figure is exactly 32 square units.

Here's the trick: the two large triangles are not similar; they are not exactly the same shape. Although they appear to be right triangles, they're not. If you look closely at the slopes of the hypotenuses, you'll see they're slightly different. The first figure's hypotenuse is a single straight line, while the second figure's hypotenuse is made up of two line segments that do not align perfectly. This creates a slight discrepancy in the slope, which accounts for the "missing" square unit. When the pieces are rearranged, this tiny difference adds up to the area of one square unit, forming the "hole" in the second figure.

It's a neat reminder that our eyes can sometimes deceive us when interpreting shapes and areas!

• Imagine a school with 5 alumni
  o Bill Doors: $1 million/year
  o Mark Bergkerzuck: $120k/year
  o Mary Sheet: $100k/year
  o Sergey Bin: $80k/year
  o Sarah Baller: $80k/year

• Average can be mean, median, or mode; They can be totally different

• Mean: Evenly distributes the total among individuals
  o Can be unrepresentative when measurements are highly skewed
  o In our example: $276k/year

• Median: Value dividing distribution into two equal parts (50th percentile)
  o In our example: $100k/year

• Mode: Most frequently observed outcome (rarely reported with numeric data)
  o In our example: $80k/year

Slide by Larry Winner, “Overview of How to Lie with Statistics”
The average market salary for MIT graduates with 0-2 years of experience is $151,000 per year.

PayScale’s methodology did not include alums with advanced degrees and only used data from graduates with bachelor’s degrees. It also excluded self-employed and contract employees.

Because the salaries of graduates from elite schools vary extensively, the study has a relatively wide margin of error, the report stated.
What conclusions can you make from this data?

Does going to MIT make you rich?
LYING WITH SURVEYS

Three questions you should ask after you read any paper:

1. Is there any bias in the sample set?
   a. Look for unconscious bias
   b. Look for conscious bias

2. What statistics are they actually talking about?

3. Are the conclusions they make supported by their reported findings (and reported statistics)?

Nominal Variables are in terms of a current dollars. For example, you’re starting salary after college might be $50,000 per year.

Real variables are in terms of some fixed commodity. Real variables measure purchasing power. If a gallon of gas costs $2.00, then we can calculate your “real” income.

\[
\text{Real Income} = \frac{\text{Nominal Income}}{\text{Price}} = \frac{\$50,000}{\$2.00} = 25,000
\]
In 2009, a gallon of gas cost $3.50

Real Gross = \( \frac{\text{Nominal Gross}}{\text{Price}} \) = \( \frac{749M}{3.50} \) = 214M (Gallons of Gas)

In 1977, a gallon of gas cost $.62

Real Income = \( \frac{\text{Nominal Gross}}{\text{Price}} \) = \( \frac{460M}{.62} \) = 742M (Gallons of Gas)

A) The chances are greater than 1 in 20 that a difference would be found if the study were repeated.

B) The probability is less than 1 in 20 that a difference this large or larger could occur by chance alone.

C) The probability is greater than 1 in 20 that a difference this large or larger could occur by chance alone.

D) The chance is 95% that the study is correct

E) None of the above
In my experience teaching many academic physicians, when physicians are presented with a single-sentence summary of a study that produced a surprising result with $P = 0.05$, the overwhelming majority will confidently state that there is a 95% or greater chance that the null hypothesis is incorrect.

What is wrong with this?

MISCONCEPTION 1

“In my experience teaching many academic physicians, when physicians are presented with a single-sentence summary of a study that produced a surprising result with \( P = 0.05 \), the overwhelming majority will confidently state that there is a 95% or greater chance that the null hypothesis is incorrect.

This is an understandable but categorically wrong interpretation because the \( P \) value is calculated on the assumption that the null hypothesis is true. It cannot, therefore, be a direct measure of the probability that the null hypothesis is false. This logical error reinforces the mistaken notion that the data alone can tell us the probability that a hypothesis is true.”

MISCONCEPTION #1

“If P=.05, the null hypothesis has only a 5% chance of being true”

Let us suppose we flip a penny four times and observe four heads, two-sided P = .125. This does not mean that the probability of the coin being fair is only 12.5%.

Null hypothesis = “coin is fair”

The p-value does not tell us the probability that the coin is fair or unfair. It tells us the probability of observing a particular outcome (four heads in a row, in this case) assuming the coin is fair.

Steven Goodman: “A Dirty Dozen: Twelve P-Value Misconceptions”
MISCONCEPTION #2

A non-significant difference (e.g., P .05) means there is no difference between groups.

- A non-significant difference only means the null effect is statistically consistent with the observation
- It does not make the null effect most likely
- The most important aspect of a study's outcome is the actual observed effect itself: how strong or weak it is, and the practical or clinical significance of this finding, regardless of the p-value.

Steven Goodman: “A Dirty Dozen: Twelve P-Value Misconceptions”
MISCONCEPTION #3

A statistically significant finding is (clinically) important

The P value carries no information about the magnitude of an effect, which is captured by the effect estimate and confidence interval.
MISCONCEPTION #4

“Studies with P values on opposite sides of .05 are conflicting”

$H_0$: Drug T has no effect
$H_1$: Drug T has a positive effect

Study I: $P=0.3$
Study II: $P=0.002$
MISCONCEPTION #5

Studies with the same P value do not provide the same evidence against the null hypothesis.

![Graph showing different results with the same P value](image)
The Basic and Applied Social Psychology (BASP) 2014 Editorial emphasized that the null hypothesis significance testing procedure (NHSTP) is invalid, and thus authors would be not required to perform it (Trafimow, 2014). However, to allow authors a grace period, the Editorial stopped short of actually banning the NHSTP. The purpose of the present Editorial is to announce that the grace period is over. From now on, BASP is banning the NHSTP.

With the banning of the NHSTP from BASP, what are the implications for authors? The following are anticipated questions and their corresponding answers.

**Question 1. Will manuscripts with p-values be desk rejected automatically?**

**Answer to Question 1.** No. If manuscripts pass the a strong case for rejecting it, confidence intervals do not provide a strong case for concluding that the population parameter of interest is likely to be within the stated interval. Therefore, confidence intervals also are banned from BASP.

Bayesian procedures are more interesting. The usual problem with Bayesian procedures is that they depend on some sort of Laplacian assumption to generate numbers where none exist. The Laplacian assumption is that when in a state of ignorance, the researcher should assign an equal probability to each possibility. The problems are well documented (Chihara, 1994; Fisher, 1973; Glymour, 1980; Popper, 1983; Suppes, 1994; Trafimow, 2003, 2005, 2006). However, there have been Bayesian proposals that at least somewhat circumvent

MANY ANALYSTS, ONE DATA SET
Abstract:

“Twenty-nine teams involving 61 analysts used the same data set to address the same research question: whether soccer referees are more likely to give red cards to dark-skin-toned players than to light-skin-toned players. Analytic approaches varied widely across the teams, and the estimated effect sizes ranged from 0.89 to 2.93 (Mdn = 1.31) in odds-ratio units. Twenty teams (69%) found a statistically significant positive effect, and 9 teams (31%) did not observe a significant relationship. Overall, the 29 different analyses used 21 unique combinations of covariates. Neither analysts’ prior beliefs about the effect of interest nor their level of expertise readily explained the variation in the outcomes of the analyses. ….

Crowdsourcing data analysis, a strategy in which numerous research teams are recruited to simultaneously investigate the same research question, makes transparent how defensible, yet subjective, analytic choices influence research results.”
